The theory and phenomenology of CP violation in hyperon decays is summarized.

## 1 Introduction

The CPT theorem was proved in 1955[1] and soon thereafter Lüders and Zumino[2] deduced from it the equality of masses and lifetimes between particles and anti-particles. In 1958 Okubo[3] observed that CP violation allows hyperons and antihyperons to have different branching ratios into conjugate channels even though their total rates must be equal by CPT. Somewhat later, this paper inspired Sakharov[4] to his famous work on cosmological baryon-antibaryon asymmetry. In fact, he called this the "Okubo effect", perhaps a better phrase than the current dull use of "direct CP violation." Pais[5] extended Okubo's proposal to asymmetry parameters in $\Lambda$ and $\bar{\Lambda}$ decays. The subject was revived in the '80s and a number of calculations were made[6,7]. Only now, over 40 years after Okubo's paper, are these proposals about to be tested in the laboratory.

The reason for the current interest is the need to find CP violation in places other than just $K_L - K_S$ complex. Only a number of different observations of CP violation in different channels will help us pin down the source and nature of CP violation in or beyond the standard model (SM). From this point of view, hyperon decay is one more weapon in our arsenal in addition to the K system, the B system, the D system, etc.

## 2 Phenomenology of Hyperon Decays

I summarize here the salient features of the phenomenology of non-leptonic hyperon decays[8]. Leaving out $\Omega^-$ decays, there are seven decay modes $\Lambda \rightarrow$

$N\pi,\ \Sigma^{\pm} \to N\pi$ and $\Xi \to \Lambda\pi$. The effective matrix element can be written as

$$i\ \bar{u}_{\bar{p}}(a + b\gamma_5)u_{\Lambda}\ \phi \tag{1}$$

for the mode $\Lambda \to p + \pi^-$, where a and b are complex in general. The corresponding element for $\bar{\Lambda} \to \bar{p} + \pi^+$ is then:

$$i\ \bar{v}_{\bar{p}}(-a^* + b^*\gamma_5)v_{\bar{\Lambda}}\phi^+ \tag{2}$$

It is convenient to express the observables in terms of S and P and write the matrix element as

$$S + P\ \sigma.\hat{\mathbf{q}} \tag{3}$$

where $\mathbf{q}$ is the proton momentum in the $\Lambda$ rest frame and S and P are:

$$\begin{aligned} S &= a\sqrt{\frac{\{(m_\Lambda + m_p)^2 - m_\pi^2\}}{16\pi\ m_\Lambda^2}} \\ P &= b\sqrt{\frac{\{(m_\Lambda - m_p)^2 - m_\pi^2\}}{16\pi\ m_\Lambda^2}} \end{aligned} \tag{4}$$

In the $\Lambda$ rest-frame, the decay distribution is given by:

$$\begin{aligned} \frac{d\Gamma}{d\Omega} = \frac{\Gamma}{8\pi}\{&[1 + \alpha < \sigma_\Lambda > .\hat{\sigma}] \\ &+ < \sigma_p > .[(\alpha + < \sigma_\Lambda > .\hat{\mathbf{q}})\hat{\mathbf{q}} + \quad \beta < \sigma_\Lambda > \times\hat{\mathbf{q}} \\ &+ \gamma(\hat{\mathbf{q}} \times (< \sigma_\Lambda > \times\hat{\mathbf{q}})]\} \end{aligned} \tag{5}$$

where $\Gamma$ is the decay rate and is given by:

$$\Gamma = 2 \mid \mathbf{q} \mid \{\mid S \mid^2 + \mid P \mid^2\} \tag{6}$$

$\alpha, \beta$ and $\gamma$ are given by

$$\begin{aligned} \alpha &= \frac{2Re(S^*P)}{\{\mid S \mid^2 + \mid P \mid^2\}}, \\ \beta &= \frac{2Im(SP^*)}{\{\mid S \mid^2 + \mid P \mid^2\}} \\ \gamma &= \frac{\{\mid S \mid^2 - \mid P \mid^2\}}{\{\mid S \mid^2 + \mid P \mid^2\}} \end{aligned} \tag{7}$$

For a polarized $\Lambda$, the up-down asymmetry of the final proton is given by $\alpha$($\alpha$ is also the longitudinal polarization of the proton for an unpolarized $\Lambda$). $\beta$ and $\gamma$ are components of the transverse polarization of proton [9].

The observed properties of the hyperon decays can be summarised as: (i) the $\Delta I = 1/2$ dominance i.e. the $\Delta I = 3/2$ amplitudes are about 5% of the $\Delta I = 1/2$ amplitudes; (ii) the asymmetry parameter $\alpha$ is large for $\Lambda$ and $\Xi$ decays, $\Xi$ decays and $\Sigma^+ \to p\pi^0$ and is near zero for $\Sigma^\pm \to n\pi^\pm$; and (iii) the Sugawara-Lee triangle sum rule $\sqrt{3}A(\Sigma^+ \to p\pi^0) - A(\Lambda \to p\pi^-) = 2A(\Xi \to \Lambda\pi^-)$ is satisfied to a level of 5% in both $s$ and $p$ wave amplitudes.

## 3 CP Violating Observables

Let a particle P decay into several final states $f_1, f_2$ etc. The amplitude for P $\to f_1$ is in general:

$$A = A_1 e^{i\delta 1} \quad + A_2\ e^{i\delta 2} \tag{8}$$

where 1 and 2 are strong interaction eigenstates and $\delta_i$ are corresponding final state phases. Then the amplitude for $\bar{P} \to \bar{f}_1$ is

$$\bar{A} = A_1^* e^{i\delta 1} \quad + A_2^*\ e^{i\delta 2} \tag{9}$$

If $\mid A_1 \mid >> \mid A_2 \mid$, then the rate asymmetry $\Delta(= (\Gamma - \bar{\Gamma})/(\Gamma + \bar{\Gamma}))$ is given by:

$$\Delta \approx -2 \mid A_2/A_1 \mid sin(\phi_1 - \phi_2) sin(\delta_1 - \delta_2) \tag{10}$$

where $A_i = \mid A_i \mid e^{i\phi_i}$. Hence, to get a non-zero rate asymmetry, one must have (i) at least two channels in the final state, (ii) CPV weak phases must be different in the two channels, and (iii) unequal final state scattering phase shifts in the two channels[9]. A similar calculation of the asymmetry of $\alpha$[10] shows that for a single isospin channel dominance,

$$A = (\alpha + \bar{\alpha})/(\alpha - \bar{\alpha}) = 2tan(\delta_s - \delta_p)\ tan(\phi_s - \phi_p) \tag{11}$$

In this case the two channels are orbital angular momenta 0 and 1; and even a single isospin mode such as $\Xi^- \to \Lambda\pi^-$ can exhibit a non-zero A. In B decays an example of a single isospin mode exhibiting CP violating rate asymmetry is $B \to \pi\pi$, i.e. In this case the two eigen-channels with different weak CP phases and different final state phases are $B \to D\overline{D}\pi \to \pi\pi$ and $B \to \pi\pi \to \pi\pi$[11].

To define the complete set of CP violating observables, consider the example of the decay modes $\Lambda \to p\pi^-$ and $\bar{\Lambda} \to \bar{p}\pi^+$. The amplitudes are:

$$\begin{aligned} S &= -\sqrt{\frac{2}{3}} S_1 e^{i(\delta_1 + \phi_1^s)} + \frac{1}{\sqrt{3}} S_3 e^{i(\delta_3 + \phi_3^s)} \\ P &= -\sqrt{\frac{2}{3}} P_1 e^{i(\delta_{11} + \phi_1^p)} + \frac{1}{\sqrt{3}} P_3 e^{i(\delta_3 + \phi_3^p)} \end{aligned} \tag{12}$$

where $S_i, P_i$ are real, $i$ refers to the final state isospin (i=2I) and $\phi_i$ are the CPV phases. With the knowledge that $S_3/S_1$, $P_3/P_1 << 1$ ; one can write[12,13]

$$\Delta_\Lambda = \frac{(\Gamma - \overline{\Gamma})}{(\Gamma + \overline{\Gamma})} \cong \sqrt{2}\ (S_3/S_1) sin(\delta_3 - \delta_1) sin(\phi_3^s - \phi_1^s)$$
$$A_\Lambda = \frac{(\alpha + \overline{\alpha})}{(\alpha - \overline{\alpha})} \cong -tan(\delta_{11} - \delta_1) tan(\phi_1^p - \phi_1^s)$$
$$B_\Lambda = \frac{(\beta + \overline{\beta})}{(\beta - \overline{\beta})} \cong cot(\delta_{11} - \delta_1) tan(\phi_1^p - \phi_1^s) \qquad (13)$$

The last one $B_\Lambda$ has the peculiar feature that it blows up as the phase shift difference vanishes. The reason is that in the limit of CP conservation $\beta + \overline{\beta} = 0$ but in the limit of no final state phase difference $\beta - \bar{\beta} = 0$. For $\pi$N final states, the phase shifts at $E_{c.m.} = m_\Lambda$ are known and are: $\delta_1 = 6^0$, $\delta_3 = -3.8^0$, $\delta_{11} = 1.1^0$ and $\delta_{31} = -0.7^0$ from the 1965 analysis of Roper et al.[14] with errors estimated at 10%. The CPV phases $\phi_i$ have to be provided by theory.

Similar expressions can be written for other hyperon decays. For example, for $\Lambda \to n\pi^0$, $\Delta$ is $-2\Delta_\Lambda$ and $A$ and $B$ are identical to $A_\Lambda$ and $B_\Lambda$. For $\Xi^- \to \Lambda\pi^-$ ( and $\Xi^0 \to \Lambda\pi^0$) the asymmetries are[13]:

$$\Delta_\Xi = 0$$
$$A_\Xi = -tan(\delta_{21} - \delta_2) tan(\phi^p - \phi^s)$$
$$B_\Xi = cot(\delta_{21} - \delta_2) tan(\phi^p - \phi^s) \qquad (14)$$

where $\delta_{21}$ and $\delta_2$ are the $p$ and $s$-wave $\Lambda\pi$ phase shifts at $m_\Xi$ respectively. Somewhat more complicated expressions can be and have been written for $\Sigma$ decays[13].

## 4 Calculating CP Phases

In standard model description of the non-leptonic hyperon decays, the effective $\Delta S = 1$ Hamiltonian is

$$H_{eff} = \frac{G_F}{\sqrt{2}}\ U_{ud}^*\ U_{us} \sum_{i=1}^{12} c_i(\mu)\ O_i(\mu) \qquad (15)$$

after the short distance QCD corrections (LLO + NLLO) where $c_i = z_i + y_i\tau (\tau = -U_{td}\ U_{ts}^*/U_{ud}\ U_{us})$, and $\mu \sim 0(1\ \text{GeV})$[15]. For CP violation, the most important operator is:

$$O_6 = \bar{d}\ \lambda_i \gamma_\mu (1 + \gamma_5) s\bar{q} \lambda_i \gamma_\mu (1 - \gamma_5) q \qquad (16)$$

and $y_6 \approx -0.1$ at $\mu \sim 1\ GeV$. To estimate the CP phases in Eq. (12), one adopts the following procedure. The real parts(in the approximation that the imaginary parts are very small) are known from the data on rates and asymmetries. The real parts of the amplitudes have also been evaluated in SM with reasonable success with some use of chiral perturbation theory(current algebra and soft pion theorems) and a variety of choices for the baryonic wave functions. The MIT bag model wave function is one such choice which gives conservative results. The same procedure is adopted for calculating the imaginary parts using $O_6$. The major uncertainty is in the hadronic matrix elements and the fact that the simultaneous fit of $s$ and $p$ waves leaves a factor of 2 ambiguity [16]. In the SM, with the Kobayashi-Maskawa phase convention[17] there is no CPV in $\Delta I = 3/2$ amplitudes; and for $\Lambda$ and $\Xi$ decays $\phi_3 = 0$. There is a small electroweak penguin contribution to $\phi_3$ which can be safely neglected. The rate asymmetry is dominated by the s wave amplitudes and the asymmetry $A_\Lambda$ is dominated by the $\Delta I = 1/2$ amplitudes. Evaluating the matrix elements in the standard way and with the current knowledge of the K-M matrix elements one finds for the decays[13,18] $\Lambda \to p\pi^-$ and $\Xi^- \to \Lambda\pi^-$:

$$\begin{aligned} \phi^s_\Lambda - \phi^p_\Lambda &\cong 3.5.10^{-4} \\ \phi^s_\Xi - \phi^p_\Xi &\cong -1.4.10^{-4} \end{aligned} \tag{17}$$

With the $N\pi$ phase shifts known to be

$$\delta_s - \delta_p \cong 7^0 \tag{18}$$

one finds for the asymmetry $A_\Lambda$ in the standard model a value of about $-4.10^{-5}$. For the $\Xi \to \Lambda\pi^-$ decay mode the phase shifts are not known experimentally and have to be determined theoretically. There are calculations from 1965 [19] which gave large values for $\delta_s - \delta_p \sim -20^0$; however, all recent calculations based on chiral perturbation theory, heavy baryon approximation etc. agree that $\delta_s - \delta_p$ lies between $1^0$ and $3^0$ [20]. These techniques have been tested in $\pi$-N scattering where they reproduce the known phase shifts within a factor of two[21]. In this case the asymmetry $A_\Xi$ is expected to be $\sim -(0.2$ to $0.7)10^{-5}$. In the Table 1, the SM results for the expected asymmetries in SM are given. Using very crude back of the envelope estimates, similar results are obtained. What is needed is some attention to these matrix elements from the Lattice community.

An experimental measurement of the phase shifts $\delta_s - \delta_p$ in $\Lambda\pi$ system will put the predictions for $A_\Xi$ on a firmer basis. There is an old proposal due to Pais and Treiman [22] to measure $\Lambda\pi$ phase shifts in $\Xi \to \Lambda\pi e\nu$, but this does not seem practical in the near future. Another technique, more feasible, it to

measure $\beta$ and $\alpha$ to high precision in $\Xi$ and $\overline{\Xi}$ decays. Then the combination.

$$(\beta - \bar{\beta})/(\alpha - \bar{\alpha}) = tan\ (\delta_s - \delta_p) \tag{19}$$

can be used to extract $\delta_s - \delta_p$. To the extend CP phases are negligible one can also use the approximate relation:

$$\beta/\alpha \approx tan(\delta_s - \delta_p) \tag{20}$$

In $\Sigma$ decays, some asymmetries are quite large[13] but in difficult to measure channels e.g. $B_\Sigma$. In $\Omega^- \to \Xi\pi$ decays the rate asymmetry is larger due to the larger $\Delta I = 3/2$ amplitudes[23]. There are no experimental proposals to measure CP asymmetries in $\Sigma$ or $\Omega^-$ decays at this time.

## 5 Beyond Standard Model

Can new physics scenarios in which the source of CP violation is not K-M matrix yield large enhancements of these asymmetries? We consider some classes of models where these asymmetries can be estimated more or less reliably [12,13]. It should be kept in mind that any estimates with new physics are at least as uncertain as SM and usually much more prone to uncertainty for obvious reasons.

First there is the class of models which are effectively super-weak[24]. Examples are models in which the K-M matrix is real and the observed CP violation is due to exchange of heavier particles; heavy scalars with FCNC, heavy quarks etc. In all such models direct CP violation is negligible and unobservable and so all asymmetries in hyperon decays are essentially zero. Furthermore, they need to be modified to accommodate the fact that direct CP violation ("Okubo effect") has now been seen in the kaon decays( the fact that $\epsilon'/\epsilon$ is not zero). In the three Higgs doublet model with flavor conservation imposed, the charged Higgs exchange tends to give large effects in direct CP violation as well as large neutron electric dipole moment [25].

There are two generic classes of left-right symmetric models: (i) Manifest Left- Right symmetric model without $W_L - W_R$ mixing[26] and (ii) with $W_L - W_R$ mixing [27]. In (i) $U^L_{KM}$ = real and $U^R_{KM}$ complex with arbitrary phases but angles given by $U^L_{KM}$. Then one gets the "isoconjugate" version in which

$$H_{eff} = \frac{G_F\ U_{us}}{\sqrt{2}} \left[ J^\dagger_{\mu L}\ J_{\mu L} +\ \eta e^{i\beta} J^\dagger_{\mu R}\ J_{\mu R} \right] \tag{21}$$

where $\eta = m^2_{WL}/m^2_{WR}$ and $\beta$ is the relevant CPV phase. Then $H_{p.c.}$ and $H_{p.v.}$ have overall phases $(1 + i\eta\beta)$ and $(1 - i\eta\beta)$ respectively. To account

for the observed CPV in K-decay, $\eta\beta$ has to be of order $4.5.10^{-5}$. In this model, $\epsilon'/\epsilon = 0$ and there are no rate asymmetries in hyperon decays but the asymmetries A and B are not zero and e.g. A goes as $2\eta\beta\sin(\delta_s - \delta_p)$. In the class of models where $W_L - W_R$ mixing is allowed, the hyperon asymmetries can be enhanced, and also $\epsilon'/\epsilon$ is not zero in general[27] (see Table 1).

In MSSM (Minimum Supersymmetric Standard Model) there are new CP violating phases and potentially new contributions to many observables. Until recently the conventional thinking was that the most relevant phase was the one in the squark LL mass terms:

$$m_{12}^2 \; \bar{\tilde{d}}_L \; \tilde{s}_L \tag{22}$$

and well constrained by $\epsilon$ so that the contribution to $\epsilon'/\epsilon$ would be less than $2.10^{-4}$ (similarly for hyperon decays). The new wisdom, painfully learnt after the new results on $\epsilon'/\epsilon$, is that this is not the whole story. There are several ways in which supersymmetric contributions can arise for $K$ and hyperon decays.

One example is the lack of degeneracy of $\tilde{d}_R$ and $\tilde{u}_R$ masses[28]. This gives rise to I-spin breaking and in turn can enhance $ImA_2$ and contribute to $\epsilon'/\epsilon$ at a level of $10^{-3}$. For hyperon decays this would lead to a mild enhancement of rate asymmetries but would have no effect on the asymmetries A being probed by E871.

Another possibility is the existence of phases in the L-R squark mass terms[29]. The effect of these on the s-d gluon dipole operator can be parameterised as:

$$\left\{a_{LR} \; \bar{d}_L \; \lambda^a \; \sigma_{\mu\nu} \; s_R \; + a_{RL} \; \bar{d}_R \; \lambda^a \; \sigma_{\mu\nu} \; s_L\right\} G^a_{\mu\nu} + h.c. \tag{23}$$

In terms of $a_{LR}$ and $a_{RL}$, $\epsilon'/\epsilon$ and $A(\Lambda)$ can be written as[30]:

$$\begin{array}{rl} \epsilon'/\epsilon \;\; \alpha & \quad Im(a_{LR} - a_{RL}) \\ A(\Lambda) \;\; \alpha \; Im(0.2 \; a_{LR} + 2.6 a_{RL}). & \end{array} \tag{24}$$

The figure shows the range of $A(\Lambda)$ for various allowed values of $a_{LR}$ and $a_{RL}$. Note that $a_{RL}$ can yield values for $A(\Lambda)$ as large as $10^{-3}$ easily probed by E871. This operator is also enhanced in models where CP violation arises thru the exchange of charged scalars such as the Weinberg model[25].

## 6 Experiments

There have been several proposals to measure hyperon decay asymmetries in $\bar{p}p \to \bar{\Lambda}\Lambda$, $\bar{p}p \to \bar{\Xi}\Xi$ and in $e^+e^- \to J/\psi \to \Lambda\bar{\Lambda}$ but none of these were approved [31]. The only approved and on-going experiment is E871 at Fermilab.

Table 1: Expectations for Hyperon CPV Asymmetries.

| | SM | 2-Higgs | FCNC Superweak | L-R-S (1) | L-R-S (2) |
|---|---|---|---|---|---|
| $\Delta_\Lambda$ | $10^{-6}$ | $10^{-5}$ | 0 | 0 | 0 |
| $A_\Lambda$ | $-4.10^{-5}$ | $-2.10^{-5}$ | 0 | $-10^5$ | $6.10^{-4}$ |
| $B_\Lambda$ | $10^{-4}$ | $2.10^{-3}$ | 0 | $7.10^{-4}$ | - |
| $\Delta_\Xi$ | 0 | 0 | 0 | 0 | 0 |
| $A_\Xi$ | $-4.10^{-6}$ | $-3.10^{-4}$ | 0 | $2.10^{-5}$ | $10^{-4}$ |
| $B_\Xi$ | $10^{-3}$ | $4.10^{-3}$ | 0 | $3.10^{-4}$ | - |

In this experiment $\Xi^-$ and $\overline{\Xi}^+$ are produced and the angular distribution of $\Xi^- \to \Lambda\pi^- \to p\pi^-\pi^-$ and $\overline{\Xi}^+$ compared. This experiment effectively measures $A_\Lambda + A_\Xi$ and will be described in detail by Kam-Biu Luk [32]. To summarize the implications for the measurement of $A_\Lambda + A_\Xi$ by E871: the SM expectation is about $-4.10^{-5}$ with a factor of two uncertainty; if new physics should contribute it could be as large as $10^{-3}$. A measurement by E871 at the $10^{-4}$ level, therefore, will already be a strong discriminant. Eventually, it will be important to know $A_\Lambda$ and $A_\Xi$ separately and the old proposals[31] should be revived.

## 7 $\epsilon'/\epsilon$ and Hyperon Decay Asymmetries

It might seem that now that $\epsilon'/\epsilon$ has been measured and direct CP violation in $\Delta S = 1$ channel been observed, a study of CP violation in hyperon decays is unnecessary and no new information will be obtained. Why is it worthwhile measuring another $\Delta S = 1$ process like hyperon decay? The point is that there are important differences and the two are not at all identical. First, there are important differences in the matrix elements. Hyperon matrix elements do not have the kind of large cancellations that plague the kaon matrix elements. The hadronic uncertainties are present for both, but are different. Next, a very important difference is the fact that the K $\to \pi\pi$ decay (and hence $\epsilon'$) is only sensitive to CP violation in the parity violating amplitude and cannot yield any information on parity conserving amplitudes. Hyperon decays, by contrast, are sensitive to both. Thus, $\epsilon'/\epsilon$ and hyperon decay CP asymmetries are different and complimentary. The hyperon decay measurements are as important and significant as $\epsilon'/\epsilon$.

## Conclusion

The searches for direct CPV are being pursued in many channels: $\Lambda \to N\pi$, B decays and D decays. Any observation of a signal would be the first outside of $K^0 - \overline{K}^0$ system and would be complimentary to the measurement of $\epsilon'/\epsilon$. This will constitute one more step in our bid to confirm or demolish the Standard Kobayashi-Maskawa description of CP violation.

Hyperon decays offer a rich variety of CP violating observables, each with different sensitivity to various sources of CP violation. For example, $\Delta_\Lambda$ is mostly sensitive to parity violating amplitudes, $\Delta_{\Sigma^+}$ is sensitive only to parity conserving amplitudes, $A$ is sensitive to both etc. The size of expected signals vary inversely with the ease of making measurements, i.e. $\Delta < A < B$. Probably because of that, the number of experimental proposals is rather small so far. The one on-going experiment Fermilab E871 can probe $A$ to a level of $10^{-4}$ which is already in an interesting range. In addition to more experiments, this subject sorely needs more attention devoted to calculating the matrix elements more reliably.

## Acknowledgment

I am grateful to my collaborators Alakabha Datta, Xiao-Gang He, Hitoshi Murayama, Pat O'Donnell, German Valencia and John Donoghue and to members of the E871 collaboration for many discussions. The hospitality of Hai-Yang Cheng, George Hou and their colleagues and staff was memorable and the atmosphere of the conference was most stimulating. This work is supported in part by USDOE under Grant #DE- FG-03-94ER40833.

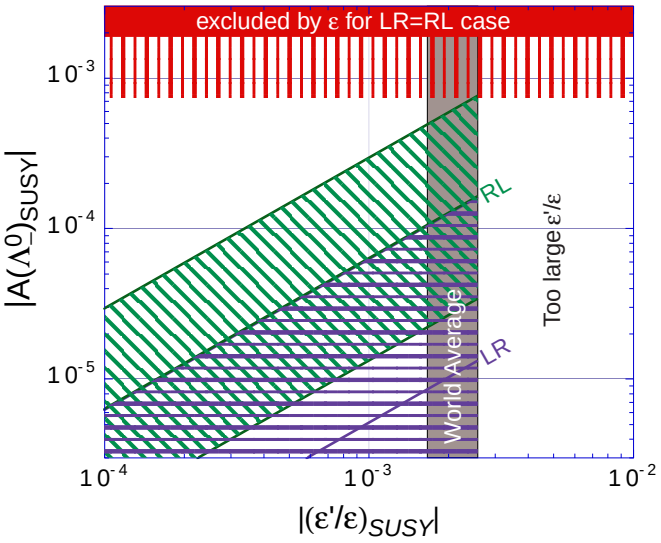

Figure 1: The allowed regions on ($|(\epsilon'/\epsilon)_{SUSY}|$, $|A(\Lambda^0_-)_{SUSY}|$) parameter space for three cases: a) only $Im(a_{LR})$ contribution, which is the conservative case (hatched horizontally), b) only Im($a_{RL}$) contribution (hatched diagonally), and c) $Im(a_{LR}) = Im(a_{RL})$ case which does not contribute to $\epsilon'$ and can give a large $|A(\Lambda^0_-)|$ below the shaded region (or vertically hatched region for the central values of the matrix elements). The last case is motivated by the relation $\lambda = \sqrt{m_d/m_s}$. The vertical shaded band is the world average of $\epsilon'/\epsilon$. The region to the right of the band is therefore not allowed.
